**Abstract.** Tabular data plays an essential role in many data analytics and machine learning tasks. Typically, tabular data does not possess any machine-readable semantics. In this context, semantic table interpretation is crucial for making data analytics workflows more robust and explainable. This article proposes Tab2KG – a novel method that targets at the interpretation of tables with previously unseen data and automatically infers their semantics to transform them into semantic data graphs. We introduce original lightweight semantic profiles that enrich a domain ontology's concepts and relations and represent domain and table characteristics. We propose a one-shot learning approach that relies on these profiles to map a tabular dataset containing previously unseen instances to a domain ontology. In contrast to the existing semantic table interpretation approaches, Tab2KG relies on the semantic profiles only and does not require any instance lookup. This property makes Tab2KG particularly suitable in the data analytics context, in which data tables typically contain new instances. Our experimental evaluation on several real-world datasets from different application domains demonstrates that Tab2KG outperforms state-of-the-art semantic table interpretation baselines

Keywords: Semantic Table Interpretation, Domain Knowledge Graphs, Semantic Profiles, One-shot Learning

#### 1. Introduction

A vast amount of data is currently published in a tabular format [1–3]. Typically, this data does not possess any machine-readable semantics. Semantic table interpretation is an essential step to make this data usable for a wide variety of applications, with data analytics workflows (DAWs) as a prominent example [4]. DAWs include data mining algorithms and sophisticated deep learning architectures and require a large amount of heterogeneous data as an input. Typically, DAWs treat tabular data as character sequences and numbers and potentially miss important information that has not been made available explicitly. This practice can lead to error-prone analytics processes and results, particularly when data analytics frameworks utilize the data from various heterogeneous sources.

Therefore, DAWs can substantially profit from the semantic interpretation of the involved data tables [5, 6].

2.7

In this context, semantic table interpretation aims to transform the input data table into a semantic data graph. In this process, table columns are mapped to a domain ontology's classes and properties; table cell values are transformed into literals, forming the data graph – a network of semantic statements, typically encoded in RDF. In the context of DAWs, semantic table interpretation can bring several advantages. First, an abstraction from tabular data to semantic concepts and relations can guide domain experts in the DAW creation [4]. Second, validation options (e.g., type inference) that become available through the semantic table interpretation can increase the robustness of DAWs [7]. Third, semantic descriptions can be employed to facilitate the explainability of the data analytics results [8]. Finally, semantic table interpretation adds structure directly usable for knowledge inference [9].

The existing approaches to semantic table interpretation do not adequately support the interpretation of tabular data for DAWs. At the core of such approaches (e.g., [10–12]) is the instance lookup task, where table cells are linked to known instances in a target knowledge graph, with DBpedia [13] being a popular crossdomain target. Subsequent steps such as property mapping are based on the results of this lookup step. However, as shown by Ritze et al. [14], only about 3\% of the tables contained in the 3.5 billion HTML pages of the Common Crawl Web Corpus<sup>1</sup> can be matched to DBpedia. In the context of DAW, the input data typically represents new instances (e.g., sensor observations, current road traffic events, ...), and substantial overlap between the tabular data values and entities within existing knowledge graphs cannot be expected.

In this article, we present Tab2KG - a novel semantic table interpretation approach. Tab2KG aims to transform a data table into a semantic data graph. As a backbone of the data graph, Tab2KG relies on an existing domain ontology that defines the concepts and relations in the target domain. To facilitate the transformation, Tab2KG introduces original lightweight semantic profiles for domains and data tables. Domain profiles enrich ontology relations and represent domain characteristics. A domain profile associates relations with feature vectors representing data types and statistical characteristics such as value distributions. To transform a data table. Tab2KG first creates a data table profile. Then, Tab2KG uses the domain and data table profiles to transform the table into a data graph using a novel one-shot learning approach.

To create domain profiles, Tab2KG uses a domain ontology and a data sample that can be obtained from an existing domain knowledge graph. Lightweight semantic profiles generated by Tab2KG can be utilized as compact domain representations and complement and enrich existing dataset catalogs. Such profiles can be generated automatically from the existing datasets and described using the DCAT<sup>2</sup> and the SEAS<sup>3</sup> vocabularies to enable their reusability. We believe that lightweight semantic profiles presented in this article are an essential contribution that can benefit a wide range of semantic applications beyond semantic table interpretation.

In summary, *Tab2KG* is driven by the following three goals, which distinguish *Tab2KG* from traditional semantic table interpretation approaches:

2.7

- Interpretation of previously unseen data: Tab2KG
  can interpret domain-specific tables in the common case where the table values are not yet
  present in existing knowledge graphs.
- Usage of lightweight semantic profiles: Tab2KG
  relies on lightweight semantic profiles with profile features which can be easily modeled as part
  of data catalogs (e.g., histograms and data types).
- Generalisation through one-shot learning: Tab2KG generalises towards new domain ontologies with a one-shot learning approach.

Consequently, our contributions presented in this article are as follows:

- We introduce lightweight semantic domain and table profiles. Domain profiles enrich relations of domain ontologies and serve as a lightweight domain representation. Semantic table profiles summarize data tables facilitating effective semantic table interpretation.
- 2. We propose the *Tab2KG* approach to transform tabular data into a data graph with one-shot learning based on semantic profiles.
- 3. We evaluate the proposed method on several real-world datasets. Our evaluation results demonstrate that *Tab2KG* outperforms state-of-the-art semantic table interpretation baselines.
- 4. We make the scripts for creating lightweight semantic profiles and transforming data tables into data graphs publicly available<sup>4</sup>.

The structure of this article is as follows: In Section 2, we introduce a running example used throughout this article. Then, in Section 3, we define the problem of semantic table interpretation, followed by the definition and creation of domain and data table profiles (Section 4). In Section 5, we describe our proposed *Tab2KG* approach and its implementation (Section 6). We present evaluation setup and results in Sections 7 and 8, followed by a discussion of our profile-based approach in Section 9. Then, we discuss related work in Section 10. Finally, we provide a conclusion in Section 11.

### 2. Running Example from the Weather Observation Domain

2.7

Tab2KG is a domain-independent approach that generalizes to previously unseen domains and data tables. There are no constraints on the data nature (e.g., sensor data, numbers, strings, ...), and we demonstrate in our evaluation how Tab2KG performs on different domains, including soccer and advertisements data. As a running example, we use the weather observation domain and a data table that provides observations of sensors measuring air conditions.

Consider the table in Fig. 1 that contains weather observation sensor data, separated by a tab character (—»). The table does not include column titles. As a human, we can observe that the first column refers to the air condition (*cloudy*, *clear*, *rain*). The second and third column may represent a time interval of the measurement (e.g., 16:30 and 17:00). The fourth column containing the values S2, S3, and S1 is hard to interpret without background knowledge.

To facilitate semantic table interpretation, *Tab2KG* relies on background knowledge regarding the target domain. Only when such background knowledge, i.e., a semantic model of the target domain, including classes and properties, already exists, it becomes possible to map the table columns to their respective semantic concepts and transform the whole table into a data graph. The required background knowledge consists of two parts: a domain ontology and a domain profile.

- The domain ontology models the specific domain of interest. In our running example, we use the Semantic Sensor Network Ontology<sup>5</sup> illustrated in Fig. 2. Amongst others, this ontology provides classes to model sensors, their observations, and corresponding time intervals.
- The semantic domain profile is a lightweight representation of typical value distributions for the ontology relations. In this example, such distributions can be obtained from prior weather observations modelled using the domain ontology. Fig. 3 gives an exemplary illustration of such a domain profile in the weather observation domain. Here, we illustrate statistical features of two observation properties (the beginning of the observation and the sensor label) using box plots and histograms. Such features can be represented

Tab2KG enables the semantic table interpretation through profile matching, which maps table columns to the ontology relations. Given the mapping, Tab2KG transforms the table into the data graph shown in Fig. 4. As we can observe, the first three columns are mapped to the observations and their time intervals. The fourth column is mapped to the sensor labels. Note that not all properties of the example domain ontology are covered by the data graph, as the domain ontology contains relations not present in the table (e.g., sosa: Observation - rdfs:label - xsd:string).

The transformation process is challenging and potentially error-prone. For example, Fig. 5 illustrates a wrong transformation result, with an incorrect column mapping and an erroneous graph structure. In this case, the sensor label "S3" was erroneously interpreted as an observation label. In addition, the beginning and end times are swapped. *Tab2KG* utilizes semantic profiles to avoid such interpretation errors.

During the evaluation, we demonstrate *Tab2KG*'s semantic table interpretation performance in two settings: (i) one table is interpreted based on the semantic domain profile built from another table, and (ii) one table is interpreted based on the semantic domain profile built from a domain ontology.

#### 3. Problem Statement

In this section, we first formally define relevant concepts. Then, we present the task of semantic table interpretation.

The entities and relations in the domain of interest (e.g., weather observation or soccer) can be represented in a domain knowledge graph.

**Definition 1.** A domain knowledge graph is a graph G = (N,R), whose nodes N represent entities and literals, and whose edges R represent relations between these nodes in the specific domain.

A domain knowledge graph consists of two sub graphs: a domain ontology and a data graph.

**Definition 2.** A domain ontology  $G_O = (N_O, R_O)$ ,  $N_O \subset N, R_O \subset R$ , where  $N_O = C \cup D \cup P$  includes a set of classes C, a set of data types D, and a set of properties  $P = P_d \cup P_o$  relevant in the specific domain, where  $P_d$  are data type properties, and  $P_o$  are object

as numerical feature vectors and included in a semantic domain description using DCAT and SEAS vocabularies.

<sup>&</sup>lt;sup>5</sup>sosa: https://www.w3.org/TR/vocab-ssn/

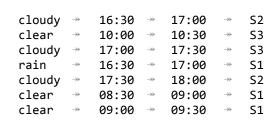

Fig. 1. Example of a data table as a tab-separated file without column titles.

properties. Data type properties relate entities to literals. Object properties relate entities to each other.

The relations represented by  $R_O = R_{OC} \cup R_{OD}$  include class relations  $R_{OC}$  and data type relations  $R_{OD}$ :

- $R_{OC}$  is the set of class relations:  $R_{OC} \subseteq C \times P_o \times C$ .
- $R_{OD}$  is the set of data type relations:  $R_{OD} \subseteq C \times P_d \times D$ .

For example, in the excerpt of Semantic Sensor Network Ontology illustrated in Fig. 2, (sosa:Sensor sosa:madeObservation sosa:Observation) is a class relation and (sosa:Sensorrdfs:label xsd:string) is a data type relation.

**Definition 3.** A data graph is a graph  $G_D = (N_D, R_D)$ ,  $N_D \subset N$ ,  $R_D \subset R$ . The nodes  $N_D = C \cup D \cup E \cup L$  include classes C, data types D, entities E and literals L. Each literal  $l \in L$  is assigned a data type  $dt(l) \in D$ . Within  $R_D$ , we distinguish between entity relations  $(E \times P_o \times E)$  and literal relations  $(E \times P_d \times L)$ .

A data table is defined as follows:

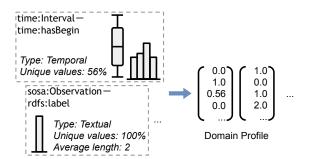

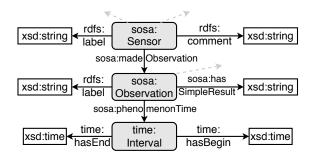

Fig. 3. An example profile of the weather observation domain. The domain profile is represented as a set of feature vectors, each containing statistical features, such as value distributions. The domain profile can also be used for visualization.

2.7

Fig. 2. Excerpt of the Semantic Sensor Network Ontology.

**Definition 4.** A data table T is a  $M \times N$  matrix consisting of M rows and N columns. A cell  $T_{m,n}$ ,  $m \in \{1, \ldots, M\}$ ,  $n \in \{1, \ldots, N\}$ , represents a data value. A row  $r_m$  is a tuple that represents a set of semantically related entities. A column  $c_n$  represent a specific characteristic of the entities in a row.

For example, the data table illustrated in Fig. 1 contains M=7 rows and N=4 columns, where the columns represent the weather conditions, time intervals, and sensor labels, and each row contains three semantically related entities: an observation, a time interval, and a sensor. The column values can belong to different data types, including text, numeric, Boolean, temporal and spatial.

Semantic table interpretation is the task of transforming a data table into a data graph.

**Definition 5.** Semantic table interpretation: Given a data table T and a domain knowledge graph G, create a data graph  $G_D^T = (N_D^T, R_D^T)$  with nodes  $N_D^T$  and relations  $R_D^T$ . Its literal values  $L^T \subseteq N_D^T$  are connected to the entities  $E^T \subset N_D^T$  and represent the values in the literal columns of T. The entities  $E^T$  are connected via entity relations in  $R_D^T$ .

#### 4. Semantic Profiles

Semantic table interpretation in *Tab2KG* does not require any instance lookup in a domain knowledge graph. Instead, *Tab2KG* uses a sample domain knowledge graph to create a lightweight semantic domain profile. This domain profile, together with a domain ontology, build reusable **domain background knowledge** that is later on used to interpret the data tables semantically.

We assume that the domain profile is representative for the value distribution regarding the data type relations it contains.

1.0

2.7

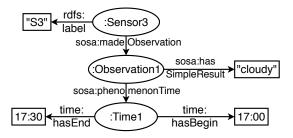

Fig. 4. Correct mapping of the third line in Fig. 1 to the ontology in Fig. 2. For brevity, we omit rdf:type relations.

Note that the entities and literals in the sample domain knowledge graph do not need to overlap with the data tables' instances to be interpreted.

Tab2KG involves the creation of two types of profiles: domain profiles and data table profiles, both represented as feature vectors and described in a semantic data catalog to facilitate their reusability. Such profiles are inspired by the dataset profiles described in [15], where statistical features are defined as an important element of a dataset profiles taxonomy. In Tab2KG, the primary purpose of the domain and data table profiles is to enable effective and efficient access to the domain and table statistics for semantic table interpretation.

We present domain profiles in Section 4.1 and data table profiles in Section 4.2. We discuss profile features in Section 4.3. Then, in Section 4.4, we describe how we represent domain and data table profiles in a semantic, machine-readable way. Finally, in Section 4.5 we provide an example of a data catalog that includes semantic profiles.

#### 4.1. Domain Profiles

For creating a domain profile, we make use of a domain knowledge graph G that contains representative values for the data type relations in the target domain. A **domain profile** is a set of data type relation profiles derived from G, where a data type relation profile is a set of statistical characteristics (features) of the literals covered by this data type relation in G's data graph  $G_D$ .

**Definition 6.** The data type relation profile  $\pi(r_D) \in \mathbb{R}^f$  of the data type relation  $r_D \in R_{OD}$  is a vector that includes f features of the literal relations covered in the domain knowledge graph G.

In brief, the profile of a data type relation  $r_D$  is a feature vector containing a set of statistics, computed using all literals corresponding to  $r_D$ .

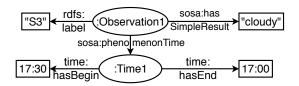

Fig. 5. Incorrect mapping of the third line in Fig. 1 to the ontology in Fig. 2. For brevity, we omit rdf:type relations.

To create a profile for the data type relation  $r_D = (c, p_d, d)$ , we utilize all literals  $l \in G_D$ , such that:  $(e, p_d, l) \in R_D$ ,  $(e, rdf : type, c) \in R_D$ , and dt(l) = d.

In our running example, in Fig. 4, the data type relation (sosa: Sensor rdfs:label xsd:string) in the domain ontology corresponds to the literal relation (:Sensor3 rdfs:label "S3") in the data graph. Therefore, we use "S3" as one of the literals to create the data type relation profile.

#### 4.2. Data Table Profiles

To facilitate semantic interpretation of a data table, we create a data table profile.

A data table profile is a set of column profiles, each representing a specific data table column. More formally, the profile of a data table T consists of a column profile  $\pi(c_n), n \in \{1, \ldots, N\}$  for each table column  $c_n \in T$  as defined in Definition 4.

A column profile is defined as follows:

**Definition 7.** A column profile  $\pi(c_n) \in \mathbb{R}^f$  of a column  $c_n$  is a vector of f statistical characteristics (features) of the values contained in that column.

We create column profiles using literal values contained in the table columns.

Column profiles and data type relation profiles are created analogously and contain the same features, presented in Section 4.3.

#### 4.3. Profile Features

Motivated by the RDF profile characteristics defined by Ellefi et al. [15], we include data types, as well as completeness and statistical features described in the following into the profiles in *Tab2KG*. The selection is motivated by the expected feature effectiveness for semantic table interpretation, i.e., matching the domain and data table profiles. We demonstrate in our

evaluation that these features can facilitate an effective matching in several application domains. This feature set can be further extended to include relevant characteristics in specific domains.

- Data type: We represent data types as binary profile features. We include fine-granular data types to facilitate the precise matching of domain and data table profiles. The following data type taxonomy includes the most common cases observed in our evaluation domains.
  - Text: Categorical, URL, Email, Other
  - **Numeric:** Integer, Decimal / Sequential, Categorical, Other<sup>6</sup>
  - Boolean
  - Temporal: Date, Time, Date Time
  - Spatial: Point, Linestring, Polygon

A data type relation or column can be assigned multiple (fine-granular) data types (e.g., integer and categorical). We provide technical details regarding the identification of fine-granular data types later in Section 6.

- Completeness: We include the number of values, the number of non-null values and the number of distinct values as a completeness indicator.
- Basic statistics: For numeric values, we include the standard deviation, mean, skewness, kurtosis and number of outliers computed using the interquartile range (1.5 IQR) rule, as well as the average numbers of characters, digits, tokens, capital letters and special characters for the literals.
- Histograms: Histograms are an effective means for RDF data summarization [17]. We create a histogram for a given number of buckets as part of the data type relation profile or column profile. As features, we add the number of literals in each bucket, in the increasing order of bucket ranges. For histogram creation, we remove the outliers detected before.
- **Quantiles:** We add quartiles and deciles to the profile (including minima and maxima).

To derive numerical features, we transform literals into numbers. The features of textual data type relations are computed based on the textual values' lengths. Temporal values are transformed into timestamps. For spatial values, we consider the line string length or the polygon area, respectively.

#### 4.4. Semantic Profile Representation

Domain and data table profiles can be represented as **semantic profiles** in RDF, as an extension of the Data Catalog Vocabulary (DCAT)<sup>7</sup> and the SEAS Statistics ontology<sup>8</sup>.

1.0

2.7

Within the DCAT vocabulary, a data catalog (dcat: DataCatalog) consists of datasets (dcat:Dataset), where a dataset is a collection of data, published or curated by a single agent. In the context of Tab2KG, both the domain knowledge graph and the data tables can be represented using dcat:Dataset. We extend the descriptions of datasets in a Tab2KG data catalog to include semantic profiles. For example, we introduce an Attribute class representing the data table columns and data type relations. We make the definitions of this vocabulary available online.

Fig. 6 provides an overview of the classes involved in representing semantic profiles. A dcat:Dataset in a Tab2KG data catalog includes several attributes. In the case of a data table profile, these attributes are the data type relations. These attributes are assigned the profile features, as presented in Section 4.3:

- 1. Data types: Data type assignments follow the previously mentioned taxonomy.
- 2. Numeric features: The numeric profile features are represented through subclasses of seas: Evaluation. In the case of quartiles, deciles, and histograms, the values come with a rank. For example, we can denote the second decile using seas: rank 2.

In the case of domain profiles, the existing mapping to the domain ontology can be modeled by connecting attributes to their corresponding classes, and data type properties [4].

Note that such semantic profiles do not only enable semantic table interpretation but can also be used to provide lightweight dataset visualizations, e.g., through box plots (quartiles) or bar charts (histograms).

#### 4.5. Running Example: Weather Data Catalog

An excerpt of an example data catalog for our running example from the weather observation domain introduced in Section 2 is shown in Fig. 7. The data catalog identified as WeatherCatalog includes two data tables (RainData and AirData). Here, the AirData data table has two columns, one of them with a column profile feature denoting the maximum value of the observation end time.

With *Tab2KG*, we can directly utilize this catalog for semantic table interpretation. Both example data tables can be interpreted through their data table profiles when a domain profile of the weather observation domain is provided.

# 5. *Tab2KG* Semantic Table Interpretation Approach

This section describes the process of semantic table interpretation.

#### 5.1. Approach Overview

Fig. 8 provides an overview of our proposed Tab2KG approach to semantic table interpretation, where a data graph  $G_D^T$  is created from a data table T. To facilitate the interpretation, Tab2KG utilizes domain background knowledge that includes a domain ontology  $G_O$  and a domain profile. The domain profile is generated in a pre-processing step from a domain knowledge graph G.

In brief, the *Tab2KG* pipeline consists of the following steps:

- 1. **Domain Profile Creation**: In a pre-processing step, we create a domain profile from a domain knowledge graph *G*.
- 2. **Data Table Profile Creation**: We create a profile of the input data table *T*.
- 3. **Column Mapping**: We generate candidate mappings between the columns of T and the data type relations in  $G_O$  using the domain profile, the data table profile, and a one-shot learning mapping function.
- 4. **Data Graph Creation**: We use the candidate column mappings and the domain ontology  $G_O$  to create a data graph  $G_D^T$  representing T's content.

In the following, we describe these steps in more detail.

#### 5.2. Domain Profile Creation

The semantic table interpretation in *Tab2KG* requires the availability of a domain profile. This profile can be inferred from a domain knowledge graph *G* as described in Section 4.1. The domain profile is created by computing the feature values given the literal relations in the domain knowledge graph. This profile can be used as a lightweight domain representation. The domain profile can be created in a pre-processing step and become available as part of a data catalog as described in Section 4.4.

Note that the domain profile does not contain any entities or literals from the domain knowledge graph *G*. The domain knowledge graph is not directly used for the semantic table interpretation.

#### 5.3. Data Table Profile Creation

From the input data table T, we create a data table profile by computing the profile features based on the column values as described in Section 4.2.

#### 5.4. Column Mapping

With the help of the domain profile and the data table profile, we create *column mappings*.

**Definition 8.** A column mapping is a mapping from a column  $c_n$  in a data table T to a data type relation  $r_D \in R_D$  in the domain ontology  $G_O: c_n \mapsto r_D$ .

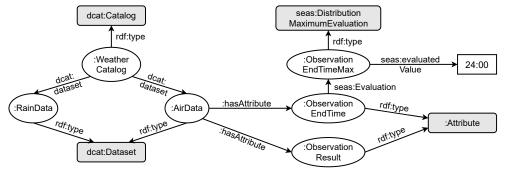

Fig. 7. Running example: Excerpt of a weather data catalog containing two data tables and an exemplified column profile feature denoting the maximum end time value (ObservationEndTimeMax).

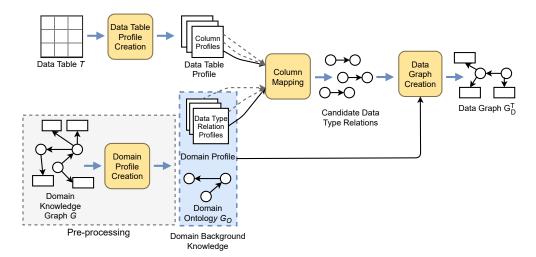

Fig. 8. An overview of semantic table interpretation with Tab2KG. Input is a data table T and a domain knowledge graph G. The output is a data graph  $G_D^T$  that represents the content of T as a data graph.

For example, we can create a mapping from column  $c_2$  of the data table illustrated in Fig. 1 to the data type relation (time:Interval - time:hasBegin - xsd:time) in the ontology illustrated in Fig. 2.

Within the Tab2KG pipeline shown in Fig. 8, we use a mapping function that creates a set of candidate column mappings  $M_{c_n}$  for each column  $c_n$  in the data table T. Given a column profile and a data type relation profile, the mapping function returns a similarity score in the range [0,1]. The mapping is created by detecting all data type relation profiles  $\pi(r_D)$  similar to the respective column profile  $\pi(c_n)$ . In this step, we only consider mappings between columns and data type relations of the same data type (numeric, textual, temporal, spatial or Boolean).

The architecture of the column mapping function is shown in Fig. 9. First, it takes two profiles as an input and performs a joint normalization, i.e., the features are normalized in a range between 0 and 1 concerning the sum of the values in both profiles. This is to ensure that the normalization happens within the same range, and this range covers all the values in both sources. If both profiles were normalized in isolation, different maximum values would be both normalised to 1.0 such that the values from different profiles were not comparable.

2.7

Then, we follow the idea used for one-shot learning for image classification [18]. Here, the task is not only to classify images into known classes (e.g., many images showing tigers) but also to generalize towards new classes (e.g., new images showing lions). That means, the underlying classifier needs to acquire features which enable the model to successfully generalize. This is done by inducing a metric that represents the domain-independent similarity between two input

1.0

2.7

feature vectors (e.g., between an unknown image and a single image showing a lion).

As we cannot train a classifier on known classes (in contrast to domain-specific approaches such as Sherlock [19] and ColNet [12]), we are in a one-shot learning setting as well: We may learn how to map column profiles to known data type relations. But when facing a new domain, our classifier needs to generalize towards unseen data type relations. In Tab2KG, the similarity between a column and a data type relation is predicted based on the experience of the similarity of other profiles learned earlier. The score to measure such similarity is facilitated by a Siamese network that encodes both profiles using the same weights and then predicts the similarity score based on the difference between the two profile encodings. As in [18], we use Rectified Linear Units for the hidden layers and a Sigmoid output layer.

#### 5.5. Data Graph Creation

Given a set of candidate column mappings  $M_{c_n}$  with similarity scores for each column  $c_n$  in the input data table T, we now assign each table column a data type relation in a greedy manner. First, we take the column mapping with the highest similarity score. Then, we remove all candidate column mappings with the particular column or data type relation. These two steps are repeated until all columns are assigned a data type relation.

From the chosen column mappings set, we create the data graph  $G_D^T$  that contains all data type relations resulting from the chosen mapping.  $G_D^T$  needs to adhere to the following four conditions:

- 1. The data graph covers all literal columns of *T*, and each literal column has exactly one mapping to a data type relation.
- 2. The set of entities in a table row is connected via entity relations.
- 3.  $G_D^T$  is minimal, i.e., no relation can be removed without invalidating the previous two conditions.
- 4. Each class relation represented by  $G_D^T$  is connected to at least one class that is part of  $M_{c_n}$ . This condition ensures semantic closeness of the data table columns and reduces the number of potential paths in the graph.

# 5.6. Creation of Training Instances for Column Mapping

For the computation of the column mapping function, we utilize a Siamese network trained once in a pre-processing step. This training process requires the extraction of positive and negative training instances. Following Definition 5 (see also Fig. 8), this step requires a set of  $(G, T, G_D^T)$  triples, where G is the domain knowledge graph, T is the data table and  $G_D^T$  is the resulting data graph. For each triple  $(G, T, G_D^T)$ , each pair of data type relations in G and a column in G is a positive training instance. We select the remaining (data type relation, column) pairs from the same knowledge graph G as negative instances.

In the first step, we synthetically create a set of  $(G, T, G_D^T)$  triples for the model training, intending to have a large dataset of positive and negative examples derived from existing data tables and knowledge graphs. Such data, i.e., a diverse set of tables and their mapping definitions to different domain ontologies, is difficult to obtain, except for manually created, task-specific research datasets [20], which are not large enough for training deep neural networks and do not provide enough topical and structural diversity. Therefore, we utilize existing knowledge graphs to create training data.

Given a set of knowledge graphs, we create a new dataset of triples  $(G_1, T, G_2^T)$ . Each input knowledge graph G is disjunctly (i.e., without shared triples) split into two KGs:  $G_1$  and  $G_2$ . As  $G_1$  and  $G_2$  do not overlap, it is ensured that the domain profile and the data table profiles used in training are not generated from the same values.  $G_1$  represents the domain knowledge graph, while  $G_2$  is transformed into a data table T. The transformation of  $G_2$  into T is based on a set of domain ontology templates. A template is a directed tree with up to k nodes, where k is a parameter. The nodes and edges of these trees are placeholders for classes and properties. A set of trees is transformed into domain ontologies by replacing these placeholders with the classes and properties of  $G_2$ . From the knowledge graph  $G_2$ , a data graph  $G_2^T$  is extracted and transformed into a data table T to create the triple  $(G_1, T, G_2^T)$ .

We aim to retrieve a set of heterogeneous data tables that represent the original knowledge graph characteristics. Therefore, the data table creation process incorporates several stochastic decisions in proportion to the knowledge graph statistics:

- Entities and entity relations (and consequently, the literal relations) in G are split at a random ratio between 25% and 75% into  $G_1$  and  $G_2$ , whereas their domain ontologies remain the same.

1.0

2.7

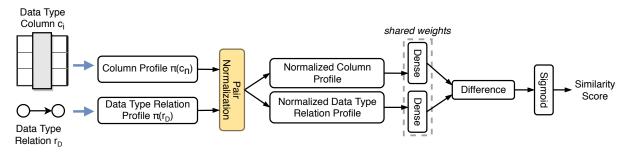

Fig. 9. Architecture of the mapping function to predict the similarity between a column  $c_n$  and a data type relation  $r_D$ .

- During the template creation, classes, and properties are assigned randomly to a domain ontology template, proportionally to their occurrence rate in G.
- Data type relations are added in the same manner, under the condition that each leaf node has to be connected with at least one data type relation. After adding the minimal required number of data type relations, we add data type relations as long as any of them are left and if a randomly generated number between 0 and 1 exceeds a predefined threshold  $\delta$ .

#### 5.7. Running Example: Data Table Creation

For our running example introduced in Section 2, Fig. 10 illustrates the transformation of a knowledge graph  $G_2$  and a domain ontology template  $\tau$  into a data table T. This transformation is performed after splitting the input knowledge graph G into  $G_1$  and  $G_2$ , where  $G_1$  and  $G_2$  represent different portions of G (e.g.,  $G_1$  contains a third observation of Sensor3). Consequently, the triple  $(G_1, T, G_2^T)$  can be used as a training example where the feature weights to map T to  $G_2^T$  based on  $G_1$ 's domain profile and T's data table profile are learnt.

#### 6. Implementation

*Tab2KG* is implemented in Java 1.8. The Siamese network is trained and applied using Keras in Python 3.7. We load knowledge graphs using Apache Jena<sup>10</sup>. We represent the column mappings inferred by *Tab2KG* in the RDF Mapping Language (RML) [21]. RML definitions are then utilized to materialize the data graph. Data tables are provided as CSV files; knowledge graphs and data graphs as Turtle (.*ttl*) files.

Each data table interpreted in *Tab2KG* runs through three pre-processing steps:

- 1. **Data type identification**: For each table column, we identify its data type(s) by trying to parse more than 90% of the values as numeric, Boolean, spatial (Well-Known Text or Well-Known Binary format [22]) or temporal (using the dateparser library<sup>11</sup>). If that is not possible, we assign the column to the text data type. For the more finegrained data types mentioned in Section 4, we utilize regular expressions (text: URL or email), follow the algorithms proposed by Alobaid et al. [16] (numeric: sequential or categorical) or analyze the parsed objects (temporal: date, time, date-time; spatial: point, line string, polygon). We follow the algorithm in [16], using the threshold of not more than 20 different categories to detect categorical text values.
- 2. Key column detection: When we transform a data table into a data graph based on the RML mapping, we create new entities. In RDF, each entity is identified by a Unique Resource Identifier (URI). It is important to understand how to create these URIs, as we need to re-use URIs referring to the same entity: For example, each row in our running example in Fig. 1 forms a new instance of sosa: Observation, together with a new URI (e.g., sosa: Observation 7), but there should only be three different sosa: Sensor URIs: sosa:SensorS1, sosa:SensorS2, sosa: SensorS3, created using the literal values assigned to the data type property rdfs:label. To create URIs, we detect data type relations representing the unique literal values of an entity as

follows: (i) the data type relation is used on all instances of the class exactly once, and the literal values are unique across their instances. Currently, we do not consider the combinations of literal relations as identifiers [23]; we leave such combinations for future work.

3. **Identifier generation**: RML transformation requires referenceable columns and instances in data tables. Therefore, we automatically generate identifiers for each column and row of the data table. If available, column names are used as part of the column identifier.

We utilize RML for storing column mappings inferred by Tab2KG in a machine-readable format such as Turtle. The RML defines subject maps that specify how to generate subjects for each row of the data table and predicate-object maps to create predicate-object pairs. In Tab2KG, the inferred column mappings are translated into the RML definitions according to the following four steps:

- 1. We create one instance of rml:source and csvw:Table each, denoting relevant characteristics for parsing the data table *T* (file location, delimiter, ...).
- 2. For each class part of the data graph  $G_D^T$ , we create a new instance of rr:TriplesMap, together with a rr:subjectMap that denotes the class as well as the target node URIs.
- 3. For each column mapping  $c_n \mapsto r_D$ , we create a rr:predicateObjectMap denoting the source column  $c_n$ , the data type property and a reference to the data type relation  $r_D$ .
- 4. For each class relation  $r \in R_{OC}$  in the domain ontology  $G_O$ , we create a rr:predicateObjectMap

connecting the respective entities and the object property.

#### 6.1.2. Running Example: RML Mapping Definitions

Listing 1 in the Appendix provides an example of the RML definitions that were automatically generated for our running example introduced in Section 2 – without the time intervals, for brevity. Instances of sosa:Sensor and sosa:Observation are created alongside their relations. The sensor labels in the third column were detected as identifiers, i.e., we create node URIs as https://www.w3.org/TR/vocab-ssn/Sensor{col3}<sup>12</sup>.

Listing 2 in the Appendix provides the resulting Turtle file representing the knowledge graph inferred from the input data table. The correct mapping of the third line shown in Fig. 4 is contained here.

#### 7. Evaluation Setup

The goal of the evaluation is to assess the performance of *Tab2KG* concerning the semantic table interpretation effectiveness using lightweight semantic profiles.

In this section, we will first describe how the data tables and domain ontologies are selected, how data table profiles and domain profiles are built and which baselines we compare to.

We make the scripts to extract the evaluation datasets and the code for training the Siamese network publicly available <sup>13</sup>.

 $<sup>^{12}\</sup>mbox{The RML}$  template definitions do not allow to use prefixes.

<sup>&</sup>lt;sup>13</sup>https://github.com/sgottsch/Tab2KG

2.7

In the real-world applications of *Tab2KG*, we require a domain ontology and a dataset that is modelled using this ontology to build the domain profile.

In our experiments, we aim to assess the perfor-

In our experiments, we aim to assess the performance of *Tab2KG* in different domains for mapping real-world tables. This evaluation requires annotated datasets which provide the tables and their ontology mappings. In the existing datasets such as SemTab [24], the tables are typically annotated using cross-domain ontologies such as DBpedia and schema.org. To facilitate evaluation, we extract domain ontologies from the tables within specific domains. This extraction results in the domain-specific parts of the existing cross-domain ontologies.

For the ontology extraction, we use two approaches: a *pairwise setting* (*P*) that uses one table and a *set-based setting* (*S*) that uses a union of tables to represent a domain. These approaches are discussed in Section 7.3.

Statistics of the domain ontologies used in the evaluation and examples of their involved classes are presented in Table 1.

#### 7.2. Datasets

The Siamese network training requires a dataset that spans over multiple vocabularies and domains to ensure generalization. However, the domain ontologies shown in Table 1 are based on schema.org and the DB-pedia ontology only. To feed and evaluate the Siamese network with data from a more diverse set of vocabularies, we created a new synthetic dataset automatically extracted from GitHub repositories dealing with knowledge graphs.

#### 7.2.1. Synthetic GitHub Dataset

The GitHub advanced code search<sup>14</sup> provides access to millions of data repositories. To collect knowledge graphs from GitHub, we selected files larger than 5KB with the specific file extensions<sup>15</sup> that contain the text "xsd" or "XSDSchema". To ensure the heterogeneity of our dataset, we limited the number of files per GitHub repository to three. Each file that was successfully parsed as a knowledge graph with more than 50 statements including at least 25 literal relations was

added to our dataset. This way, we obtained 3,922 files.

1.0

2.7

4.5

We set the parameter for maximum tree size k=3, and the parameter for adding data type relations  $\delta=0.2$ . The knowledge graphs set was split into a training set (90%) and a test set (10%). Knowledge graphs from the same repository were not included in the same set.

#### 7.2.2. Test Datasets

We use the following datasets for evaluating our approach:

- GitHub (GH): The test split of the synthetic GitHub dataset, without a restriction on the used vocabularies
- Soccer (So): 12 data tables regarding soccer players and their teams, annotated with the *schema.org* vocabulary [20].
- Weapon Ads (WA): 15 data tables about weapon advertisements, annotated with the *schema.org* vocabulary [25].
- **SemTab** (**ST**): A collection of 2, 281 data tables extracted from the T2Dv2 web table corpus, Wikipedia and others, annotated with the DBpedia ontology [24].
- SemTab Easy (SE): A subset of ST, including those 676 data tables whose columns are mapped to one class only. Only classes appearing in the T2KMatch corpus [26] are included.

For all data tables contained in these datasets, we set the following constraints:

- 1. The input table file is parseable as a CSV file without errors.
- 2. There are no classes that are instantiated multiple times in the same row. This condition is to avoid cyclic structures. We discuss limitations regarding cyclic structures in Section 9.1.
- 3. There is no pair of columns with identical values in the same table. This condition is to avoid randomness during the evaluation.
- 4. The table has at least two columns which are mapped to a data type relation. This condition is to ensure that the semantic table interpretation task does not become trivial in such cases.

Following the process to create data tables via domain ontology templates described in Section 5.5, the GH data tables did not violate these conditions. Also, these conditions were not violated by the So and WA data tables. In the case of the SemTab data tables, we had to skip 3,017 non-parseable data ta-

$\mathbf{ST}_S$ , $\mathbf{SE}_S$ : Play	DBpedia	6	15	Person, Language, Writer, MusicalArtist, Album
				:

bles (e.g., because of column values containing nonescaped delimiters such as in "Bret "Hitman" Hart", 2, 233 cyclic data tables (e.g., mathematicians and their supervisors), 520 data tables with identical column values (e.g., columns mapped to dbo:birthDate and dbo:birthYear but with identical values) and 6, 179 data tables with one column only.

#### 7.3. Profile & Test Data Generation

It is important to emphasize the difference in the evaluation setting compared to typical evaluation using the previously mentioned datasets such as ST: In the experiments conducted by [20, 27, 28], target generalpurpose knowledge graphs such as DBpedia or Wikidata are given. Each data table in the test set is then mapped to the nodes in such a knowledge graph. In our evaluation setting, we assume that no data instances are given, i.e., an instance lookup is not possible.

Instead, a domain profile and a domain ontology are provided which are derived via the pairwise and the set-based setting. Fig. 11 exemplifies these two approaches which are described in more detail in the following. While we consider pairs of data tables in the pairwise setting, we create a domain ontology based on a set of tables in the set-based setting.

#### 7.3.1. Pairwise Setting

In the pairwise setting, we select data table pairs, such that one data table mimics the domain knowledge graph from which we can derive a domain profile.

Following our setting defined in Definition 5 and illustrated in Fig. 8, the datasets are transformed into a set of triples  $(G, T, G_D^T)$ , consisting of a data table T, a domain knowledge graph G and the mapping definition which transforms data table T into the data graph  $G_D^T$ . Technically, we extract a set of test instances, consisting of (i) a .ttl file representing the domain knowledge graph G, and (ii) a .csv file representing the data table T and a .rml file representing the mapping from T to G's domain ontology. To transform the datasets into such test instances, we identify pairs of data tables where the columns of the first data table are a subset of the second data table's columns (i.e., the columns of the first data table are all mapped to data type relations which also exist in the column mapping of the second data table). Then, the second data table represents the domain knowledge. Table 2 provides an overview of the datasets used during training and evaluation under these conditions.

#### 7.3.2. Set-based Setting

In the set-based setting, we create a set of domain ontologies, each based on a set of data tables. For So and WA, we create one domain ontology each, based on all available data tables. In the case of ST and SE, we create several domain ontologies by grouping together data tables based on the class which most columns are mapped to. We only consider domain ontologies from at least 10 data tables and with at least five data type relations. Due to the diversity of domains in the GitHub data set, we do not evaluate GH with the set-based setting.

Table 1 provides an overview of the domain ontologies used in our evaluation.

#### 7.4. Baselines

We compare Tab2KG against the following three semantic table interpretation baselines:

- DSL: The Domain-independent Semantic Labeler [20] uses logistic regression on a set of

2.7

# Domain Ontology

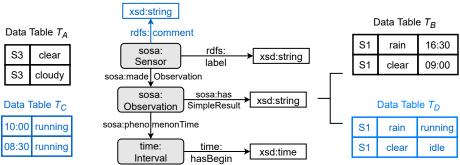

Fig. 11. Comparison of the pairwise (black) and the set-based setting (black and blue) for creating training and test instances. In the pairwise setting, one data table  $(T_B)$  represents the domain knowledge of the other data table  $(T_A)$ . In the domain ontology approach, we first create a domain ontology from a set of data tables  $(T_B \text{ and } T_D)$  and then interpret several data tables  $(T_A \text{ and } T_C)$  against the domain ontology each. In this example, "running" and "idle" are comments (rdfs:comment) about specific sensors.

#### Table 2

Datasets used in the evaluation based on the pairwise setting. # is the number of  $(G, T, G_D^T)$  triples that we generated. The other columns contain average values. For example, the tables (T) in the ST dataset have about four columns on average, while their paired domain knowledge graphs have 5.5 data type relations on average. Following the pairwise extraction process, the number of data type relations in the domain knowledge graphs is always equal or higher than the number of columns in the paired tables.

		Tables	Domain Kno	wledge Graphs
Dataset	#	Columns	Data Type Relations	Class Relations
GitHub <sub>P</sub> (Training)	8,078	2.18	3.03	1.35
<b>GH</b> <sub>P</sub> : GitHub (Test)	891	2.24	3.16	1.44
So <sub>P</sub> : Soccer	15	6.25	9.38	2.75
<b>WA</b> <sub>P</sub> : Weapon-Ads	16	10.57	11.2	4.4
$\mathbf{ST}_P$ : SemTab	233	4.09	5.54	1.26
$\mathbf{SE}_P$ : SemTab Easy	125	4.2	5.53	0.0

hand-crafted features; some of them compare value pairs at the instance-level. It has been shown to outperform previous approaches such as the SemanticTyper [29]. We train *DSL* on the same GitHub training data set as *Tab2KG*.

- DSL\*: The Domain-independent Semantic Labeler without using value similarity at the instance level. In contrast to Tab2KG and the other baselines, DSL utilizes a domain-specific data graph. As Tab2KG is solely based on the domain profile, DSL is in an advantageous setting that does not entirely reflect our setting. Therefore, we remove features at the instance-level for the DSL\* baseline.
- **T2KMatch**: T2KMatch [26] performs semantic table interpretation on the instance level. In contrast to other approaches [10, 11, 28] that rely

on a costly knowledge graph lookup at runtime, *T2KMatch* creates an index over the instances of frequently used DBpedia classes and is thus commonly used as a baseline for semantic table interpretation approaches [12, 30, 31]. It combines a ranking of entities found in the lookup phase for column type identification and data type-specific similarity measures (Levenshtein distance for strings, deviation for numbers, and deviation of years for dates) for property identification. *T2KMatch* assumes that a table only describes one entity class at a time and thus does not consider class relations.

#### 8. Evaluation Results

2.7

In this section, we describe the training performance and the evaluation results based on the evaluation setup described before.

#### 8.1. Accuracy of the Column Mapping Function

We train our Siamese network on the GitHub training dataset for 1,000 epochs, a batch rate of 100 and a learning rate of 0.0001, following Hsiao et al.'s approach for one-shot image classification [32]. We apply an early stopping criterion if the validation accuracy has not improved within 100 epochs. We use 256 dimensions for the hidden layer. 10% of the training dataset are used for validation. The feature vectors contain histograms with 10 buckets.

After training for all epochs on the synthetic training dataset, the Siamese network has an accuracy of 0.959 and a loss (binary cross-entropy) of 0.149 on the validation set. On the test set, it achieves an accuracy of 0.952, when treating scores of greater than 0.5 as candidates for column mapping.

#### 8.1.1. Hyperparameter tuning

To identify the best combination of hyper parameters, we had first performed a grid search over the number of hidden layers and their dimensions. The results with respect to the classification accuracy are shown in Table 3. Following these results, using one hidden layer is sufficient, and we set its dimension to 256 as noted before.

Table 3

Grid search results (accuracy on the test set) over the number of hidden layers and their dimension. Higher accuracy values are marked darker.

			Hidd	en Laye	rs Dime	nsion	<b>Hidden Layers Dimension</b>										
		16	32	64	128	256	512										
# Hidden	1	0.947	0.943	0.949	0.950	0.952	0.937										
Lavore	2	0.935	0.942	0.946	0.948	0.939	0.907										
Layers	3	0.891	0.930	0.909	0.934	0.939	0.821										

#### 8.1.2. Ablation study

To determine the effect of the selected features on the model's performance, we have performed an ablation study where we trained the Siamese network after removal of specific feature groups as listed in Section 4.3. Table 4 shows the model's classification performance on the GH test set. As expected, the com-

Table 4

Ablation study: Number of true positives (TP), false positives (FP), true negatives (TN), false negatives (FN) and accuracy (Acc.) on the test set.

	TP	FP	TN	FN	Acc.
All features	1,873	125	1,810	62	0.952
No data type features	1,895	251	1,684	40	0.924
No completeness features	1,865	141	1,794	70	0.945
No basic statistical features	1,822	194	1,741	113	0.921
No histograms and quantiles	1,862	132	1,803	73	0.947

bination of all selected features into the profiles leads to the highest accuracy. Among the different feature groups, the removal of the basic statistics features leads to the highest drop in performance. In general, the ablation study demonstrates that all features contribute to increase the accuracy of Tab2KG.

#### 8.2. Semantic Table Interpretation Results

We evaluate the performance of the semantic table interpretation achieved by Tab2KG compared to the baselines. Table 5 shows how the approaches perform on the different datasets, measured using accuracy, i.e., the percentage of the columns correctly mapped to data type relations and correctly identified class relations. We do not evaluate the performance of T2KMatch on other datasets than SE, as T2KMatch assumes one entity class per table only.

As we can observe in Table 5, the accuracy of the approaches varies considerably across the datasets, which can be explained by the different domain ontology and dataset characteristics shown in Table 1 and Table 2.

All methods perform worst on the WA dataset, which has the most columns, data type relations and class relations within the datasets and domain ontologies. This result unsurprisingly demonstrates that semantic table interpretation gets more difficult the more columns and relations are involved. In all cases except for the GH dataset, where Tab2KG and DSL show similar performance, Tab2KG achieves higher accuracy than the baselines concerning column mapping. Even though Tab2KG utilizes less information than DSL, Tab2KG performs better by 10 percentage points on average on this task.

The semantic interpretation of tables with domain ontology that were created with the set-based setting is more difficult than with the pairwise setting (*Tab2KG* accuracy: 0.84 vs. 0.66). While the domain ontolo-

14

16

41

35

49

50

42 47 48

### Table 5

Semantic table interpretation performance of Tab2KG, compared to the baselines on five datasets. We report the accuracy, i.e. the percentage of correctly identified data type relations  $(R_{OD})$  and class relations  $(R_{OC})$  in the datasets. Averages are computed in relation to the number of class relations plus data type relations in the datasets. T2KMatch is only evaluated on  $SE_P$  and  $SE_S$ , as it assumes one entity class per table only.

	$\mathbf{GH}_{P}$	Sop	$\mathbf{So}_{S}$	$WA_P$	$WA_S$	$\mathbf{ST}_P$	$ST_S$	$\mathbf{SE}_{P}$	$\mathbf{SE}_{S}$	Average <sub>P</sub>	Average <sub>S</sub>	Average
DSL	0.89	0.56	0.52	0.40	0.39	0.75	0.51	0.81	0.56	0.79	0.52	0.62
DSL*	0.87	0.45	0.46	0.44	0.36	0.68	0.52	0.75	0.59	0.76	0.54	0.61
T2KMatch	-	-	-	-	-	-	-	0.41	0.35	0.41	0.35	0.36
Tab2KG	0.89	0.69	0.54	0.49	0.43	0.81	0.66	0.84	0.69	0.84	0.66	0.72

gies of the set-based setting provide richer domain knowledge, the increased number of classes and relations, i.e., the increased number of candidate mappings, leads to more misinterpretations.

Surprisingly, DSL is also outperformed by DSL\* in three cases  $(WA_P, ST_S, SE_S)$ . To explain this behavior, we have computed the percentage of table values that also appear in the mapped data table relations:  $GH_P$  (33.38%),  $So_P$  (16.92%),  $ST_P$  (14.67%),  $SE_P$ (10.63%), WA<sub>P</sub> (2.65%). This observation shows that profile-based semantic table interpretation can outperform instance-level approaches when the overlap between the data table and the instances in the domain knowledge graph is low.

Second, we assess the results of the column mapping (percentage of correctly mapped columns to the data type relations  $R_{OD}$ ) and the graph creation (correctly identified class relations  $R_{OC}$ ) in isolation. We report the results achieved by Tab2KG in comparison to the baselines in Table 6 (pairwise) and in Table 7 (set-based). In the case of column mapping in the pairwise setting, Tab2KG performs best on average, outperforming DSL by 4 percentage points. A similar distribution of results, but with less accuracy, can be observed in the set-based setting. In general, the class relation mapping results in less accuracy than the column mapping. One reason is that errors propagate along the pipeline, i.e., a wrongly mapped data type relation invokes an erroneous class relation mapping.

#### 8.3. Error Analysis

By inspection of the results, we have identified two typical sources of erroneous results in *Tab2KG*:

- Value formatting: For example, the soccer dataset has data tables with column values such as "Germany", whereas the domain knowledge graphs had "GER" as a country label. Thus, the respective profile features were highly different. In the case of high-quality domain knowledge graphs that, for example, distinguish between labels and abbreviations, the error rate should be lower.

- Data type differences: For example, the SemTab dataset has elevations of mountains both denoted via integer values ("5291") and as text ("2,858 ft (871 m)"). Again, the proper use of an ontology and its rdfs:range constraints on properties should alleviate this problem.

Overall, our evaluation results demonstrate that domain profiles in combination with one-shot learning adopted by Tab2KG are an effective method for semantic table interpretation. This method does not require any instance lookup and achieves the highest accuracy on several datasets compared to the baselines.

#### 9. Discussion

In this article, we presented Tab2KG – an approach for tabular data semantification. Tab2KG relies on domain profiles that enrich the relations in a domain ontology and serve as a lightweight domain representation. Tab2KG matches these profiles with tabular data using one-shot learning. Our evaluation shows that Tab2KG outperforms the baselines for semantic table interpretation of five real-world datasets. In future work, we plan to consider integrating user feedback into the *Tab2KG* pipeline to support an extension of the domain ontology in cases where tabular data contains previously unseen relations.

The representation of data tables as data graphs opens up several possibilities for making the lives of data scientists easier - with benefits including increased efficiency and robustness of data analytics workflows. Automating semantic table interpretation, Tab2KG takes an essential step in assisting domain experts and adds an important layer of abstraction to DAWs.

#### 9.1. Limitations

We identified few limitations of *Tab2KG*, which can be attributed to the idea of using semantic lightweight dataset profiles, without requiring knowledge about particular data instances.

### 9.1.1. Column Mapping without Knowing the Dataset Instances

In contrast to approaches that perform semantic table interpretation at the instance level, i.e., with the help of the instance lookup in the domain knowledge graph, Tab2KG derives column mappings from statistical features in the domain profile. We have identified two limitations to this approach:

- Cyclic class relations: Currently, we do not address cyclic relations in the domain ontology, as for example (dbo¹6:Event dbo:nextEvent dbo:Event). Consider Fig. 12, where the second column provides the follow-up event of the event in the first column. Even if *Tab2KG* identifies the correct mapping for the third column to

- Class relations connecting the same classes: We do not have a decision criterion for distinguishing between class relations that connect the same subject and object classes. For example, consider the two object properties dbo:leader and dbo: viceLeader mapped to the second column in Fig. 13, both connecting countries to politicians. Only via statistical features extracted from the data table (which may only include the politician's name) it does not appear possible to decide if Kamala Harris is the president or the vice president of the United States.

Olympics 2004 \*\* Olympics 2008 \*\* Athens Olympics 2012 \*\* Olympics 2016 \*\* London

Fig. 12. Cyclic class relation: Did the London Olympic Games happen in 2012 or in 2016?

### 9.1.2. Correlations between Columns and Data Type Relations

Our data table profiles consist of column profiles, i.e., the features of the single columns are computed in

the property dbo:locationCity, we cannot tell if the third column maps to the location of the entity in the first or the second column.

<sup>16</sup>http://dbpedia.org/ontology/

2.7

Fig. 13. Class relations connecting the same classes: Is Kamala Harris the president or the vice president of the US?

isolation (the same applies to domain profiles and data type relations). Such column profiles can be efficiently computed and added to the dataset profile. However, the dependencies between columns may hold additional knowledge. Consider the running example in Fig. 1 where the time in the second column (begin time) does always precede the time in the next column (end time), i.e., there is a correlation between the values in these two columns.

We have decided against the inclusion of correlation features into the domain and data table profiles because of the following reasons: First, correlations are often implicitly captured by the column profiles (e.g., in Fig. 1, the second column's mean value is less than the third column's mean value). Second, the variety of data types requires different correlation and dependency measures that are hard to compare. Third, we observed that the number of column pairs heavily exceeds the number of potentially meaningful correlations in our datasets. For example, consider the football dataset where the length of the first names may be compared to the length of last names, team names, the number of goals, ..., potentially leading to correlations by chance. Fourth, the computation and semantic representation of all possible column combinations are impractical due to the quadratic number of pairwise comparisons.

We also perform data type identification for the columns in isolation. The combination of columns could be used to infer richer data types (e.g., when a date is split into a year, month and day column). We leave such potential optimisations where columns are not just considered in isolation for future work.

### 9.1.3. Asymmetry between Domain Profiles and Data Table Profiles

The domain profile and the data table profile can vary, even though they represent the same knowledge. Consider our running example of weather observations. In the table shown in Fig. 1, three rows refer to the sensor labeled "S1" but only two rows refer to the other sensors. When modeled as a knowledge graph following the mapping shown in Fig. 4, each sensor is modeled precisely as one node in the knowledge graph. Consequently, the statistical characteristics related to

the sensors vary between the data table profile and the domain profile.

1.0

2.7

# 9.1.4. Dependency on the availability and representativeness of the domain profile

*Tab2KG* relies on the availability of domain-specific data. The profile-based approach of *Tab2KG* specifically targets domains of interest which are concise and narrower in scope than existing cross-domain ontologies. As demonstrated in the evaluation, the semantic table interpretation performance decreases when the number of classes and relations increases.

The domain knowledge and the data table to be interpreted need to reflect similar value distributions to avoid misinterpretation. For example, a data profile solely built from weather observations collected in the night is not expected to entirely generalise to day time observations. In this case, the statistical features of time-related data type relations follow a distribution that is not representative of the whole domain and thus the profiles will most likely not be matched.

#### 9.2. Lightweight Semantic Dataset Profiles

Lightweight semantic profiles generated by *Tab2KG* can be utilized as a compact domain and dataset representation to complement and enrich existing dataset catalogs. Such profiles can be generated automatically from the existing datasets and described using the DCAT<sup>17</sup> and the SEAS<sup>18</sup> vocabularies to facilitate their reusability. We believe that lightweight semantic profiles presented in this article are an essential contribution that can benefit a wide range of semantic applications beyond semantic table interpretation.

Differences in value representations such as value formatting and data types, the representativeness of the domain profile, as well as the dataset characteristics (number of columns in the data table as well as the number of classes and relations in the domain ontology) are the decisive factors to perform semantic table interpretation without instance-lookup and with lightweight profiles.

The profiles of *Tab2KG* are extensible. For example, header values, language-specific information or value embeddings can be used as a source of additional profile features in future work.

#### 10. Related Work

2.7

This section provides an overview of related approaches in the areas of dataset profiling and semantic table interpretation.

Given the growth of data available on the Web and in industrial data lakes, there is a high demand for dataset profiling, e.g., for creating data catalogs [33]. The profile features typically belong to several categories, including statistical observations at the instance and schema level [15, 34]. Such features are not restricted to the initially defined schemas. For example, Neumaier et al. demonstrate how user interaction and search functionalities profit from the inclusion of spatio-temporal features into a dataset profile [35]. For tabular data, other approaches for dataset profile enrichment include the generation of table titles [36] and schema labels [37]. The inferred relation-specific rules and observations can further verify the data quality and become part of dataset profiles [38, 39].

Recently, approaches to annotate tabular data with concepts from a knowledge base to predict column types gained increased attention. In the following, we introduce approaches for semantic table interpretation and the methods they use.

Instance-level lookup. Most semantic table interpretation tools require access to a target knowledge graph, as they link data table cells to its resources [2]. Such approaches on the instance-level have recently been driven by the SemTab Challenge [24, 40], which explicitly postulates a cell-entity annotation (CEA) task, where labels in data table cells are linked to entities in a target knowledge graph. The subsequent steps of column-type annotation (CTA) and columns-property annotation typically build upon the CEA results.

Several approaches are based on entity lookup (ColNet [12], MantisTable [11], LinkingPark [27], DAGOBAH [41, 42], MTab [10], T2KMatch [26], CSV2KG [43], TableMiner+ [28], and the work by Zhang et al. [30]), with different (combined) query strategies, including URL matching [43], (partial) string lookup [11, 27, 42], string similarity [10, 26, 30, 42], spelling correction [27] or the use of named entity linking tools [11]. After linking data table cells to resources in the knowledge graphs, the CTA is typically decided through voting or counting [10, 12, 27], ranking [11, 28, 43] or clustering [42]. ColNet and TableMiner+ apply learning strategies to reduce the number of lookup tasks required for detecting the class of the entities represented by a column. MantisTable

and CSV2KG utilize concept graphs in their ranking to identify the most-specific sub classes. Also, identifying properties represented by the data tables typically relies on the CEA and additional knowledge graph lookups. For example, MTab does pairwise queries between entities identified in different columns to identify potential entity relations. To identify literal relations, MTab and TableMiner+ row-by-row compute data-type specific similarities between the literals in the target knowledge graph and the cell values. CSV2KG also involves the target ontology in this step. Sherlock [19] is a system that performs CTA and does not rely on CEA. However, it extracts column features for training a neural network, which is solely trained on DBpedia and explicitly predicts one of the selected DBpedia classes.

The reliance on entity linking with the target know-ledge graph makes these approaches unsuitable in settings where data tables only contain previously unseen data, which is a common issue [14]. Even if the data instances in the data table are not entirely unknown, these approaches do not perform well when the number of matching entities drops [12]. Another thing these approaches have in common is the reliance on a large underlying knowledge base such as DBpedia and stable lookup services. In contrast, Tab2KG does not require access to the target knowledge graph after the domain profile has been created.

**Subject column detection.** Several approaches [11, 28] for semantic table interpretation assume the existence of a subject column, i.e., the main column of the data table where every other column is directly connected to. The subject column detection is typically identified through a set of statistic features. Approaches relying on a subject column do not consider the involvement of any classes which are not directly represented in the data table (for example, consider Fig. 1, but without the first column). *Tab2KG* utilizes a graph-based approach where such class relations can be found.

Column titles. Some data tables come with column titles, which may indicate respective classes or properties. Efthymiou et al. [31] propose a method based on ontology matching, where one column title defines the class label, and other column titles represent property labels. Domain-independent Semantic Labeler [20], DAGOBAH [42] and TableMiner+ [28] exploit column titles as one of their features. *Tab2KG* does not require any column titles. This way, we ensure the generalizability for data tables without headers and language-independence.

2.7

2.7

**Data type restrictions.** Data tables contain data of various types, and thus there are approaches specific to some of them. For example, EmbNum+ [44] transforms data table columns with numeric values into embedding vectors. Alobaid et al. demonstrate that using more fine-grained numeric data types increases semantic table interpretation performance for numeric column values [16]. For the interpretation of crosslingual textual values, Luo et al. propose using several translation tools [45]. *Tab2KG* aims at the interpretation of data tables as a whole without restricting to particular data types or languages and thus establishes profiles that do not depend on particular data types or languages.

**User feedback.** Instead of relying on fully-automated approaches for semantic table interpretation, which may be error-prone due to the challenges involved in this task, manual or semi-automated approaches rely on user feedback. Karma [46], Odalic [47], and ASIA [48] are interactive tools that let users decide on the correctness of suggested table annotations and thus achieve high precision, but demand both time and expertise from the user. *Tab2KG* is a fully-automated approach for semantic table interpretation that does not require user interventions.

Domain-independent semantic table interpretation. Domain-independent approaches are not restricted to specific target knowledge graphs. Instead, they learn domain-independent similarity features to generate the mapping. The SemanticTyper [29] scores similarity between columns and data type relations based on handcrafted features for numeric and textual values. Based on similar features, the Domainindependent Semantic Labeler [20] adopts machine learning and handcrafted features to predict the similarity between a column and a class in the domain knowledge graph. Taheriyan et al. [49] generate a ranked list of potential column mappings learned from a sample of the domain ontology, which is then presented to the user. While both approaches are flexible concerning the target domain, Tab2KG aims to use only features present in the dataset profiles.

#### 11. Conclusion

This article presented *Tab2KG* - an approach for semantic table interpretation based on lightweight semantic profiles. *Tab2KG* relies on domain profiles that enrich the relations in a domain ontology and serve as a semantic domain representation. *Tab2KG* matches

these profiles with the tabular data profiles using oneshot learning approach. Our evaluation on five realworld datasets shows that our approach outperforms the baselines for semantic table interpretation. In future work, we plan to consider integrating user feedback into the *Tab2KG* pipeline to support an extension of the domain ontology in cases where tabular data contains previously unseen relations.

  rr:template "https://www.w3.org/TR/vocab-ssn/Observation{rowNumber}";
  ]
] .
ex: Mapping1 a rr: TriplesMap;
rml:logicalSource ex:File ;
rr:subjectMap [
 rr:class sosa:Observation ;
 rr:template "https://www.w3.org/TR/vocab-ssn/Observation{rowNumber}" ;
] .
```

Listing 1: A working example of an RML file transforming the data table given in Fig. 1 ("sky\_sensors.tsv") into the data graph indicated in Fig. 4. To perform the transformation, the table needs to be pre-processed: the column titles "col0",...,"col3" were added, and a "rowNumber" column. For brevity, we skip the mapping of the second and third column to time: Interval.
